13. ABSTRACT (Maximum 200 words)

A coarse measure of a discrete signal's power distribution vs. frequency is its "spectral tilt," which we define as the slope of least-squares linear fit to the log power spectrum ($0 \leq \omega \leq \pi$ rads/sec). One application of calculating spectral tilt is to help discriminate between voiced and unvoiced/silent time segments while processing sampled speech signals. When linear predictive coding (LPC) of speech is used to model its short-time spectrum, it is computationally more efficient to calculate spectral tilt directly from the LPC model parameters instead of from the log power spectrum. In this paper we present methods for calculating spectral tilt from cepstral coefficients, pole values, and polynomial coefficients. These methods are all based on calculating spectral tilt as a weighted sum of cepstral coefficients.

Abstract

A coarse measure of a discrete signal's power distribution vs. frequency is its "spectral tilt", which we define as the slope of least-squares linear fit to the log power spectrum ($0 \leq \omega \leq \pi$ rads/sec). One application of calculating spectral tilt is to help discriminate between voiced and unvoiced/silent time segments while processing sampled speech signals. When linear predictive coding (LPC) of speech is used to model its short-time spectrum, it is computationally more efficient to calculate spectral tilt directly from the LPC model parameters instead of from the log power spectrum. In this paper we present methods for calculating spectral tilt from cepstral coefficients, pole values, and polynomial coefficients. These methods are all based on calculating spectral tilt as a weighted sum of cepstral coefficients.

Introduction

Calculation of linear spectral tilt has been of interest to scientists in various disciplines [1-2], as it provides a coarse measure of a signal's power distribution vs. frequency. Given z -domain transfer function $H(z)$ we define spectral tilt to be m_{opt} , the slope of line $y(\omega) = m_{opt}\omega + b_{opt}$ that best fits the log power spectrum $\ln|H(e^{j\omega})|^2$ over the range $0 \leq \omega \leq \pi$, by the method of least-squares. That is, when error E is defined as

$$E = \int_0^\pi \left\{ m\omega + b - \ln|H(e^{j\omega})|^2 \right\}^2 d\omega,$$

E is minimum when $b = b_{opt}$ and $m = m_{opt}$. In the continuous-frequency case, calculating spectral tilt using this formula is difficult except for the simplest $|H(e^{j\omega})|^2$. An approximation to the spectral tilt is usually found from M samples of $\ln|H(e^{j\omega})|^2$, taken uniformly over the range $0 \leq \omega \leq \pi$. Estimating spectral tilt in this manner falls within the general class of least-squares polynomial interpolation [3], and estimation error is reduced to zero as $M \rightarrow \infty$. When $H(z)$ is in the form of an all-pole model,

$$H(z) = \frac{G}{(1 - p_1 z^{-1})(1 - p_2 z^{-1}) \cdots (1 - p_N z^{-1})},$$

it is advantageous to find m_{opt} from the N pole values directly, without first having to calculate samples of $\ln|H(e^{j\omega})|^2$. This not only reduces the number of calculations required, but also provides an exact measure of spectral tilt of the LPC log power spectrum. The rest of this paper deals with estimating m_{opt} from various LPC filter parameters, such as the pole values $\{p_1, p_2, \dots, p_N\}$.

Background

Let us represent the spectral tilt of $S(\omega) = \ln|H(e^{j\omega})|^2$ using functional notation: $m = \text{Tilt}\{S(\omega)\}$. The underlying principle to our method is the linearity property of least-squares spectral tilt calculation.

That is, if $S(\omega) = a_1 S_1(\omega) + a_2 S_2(\omega)$, then

$$\begin{aligned} \text{Tilt}\{S(\omega)\} &= \text{Tilt}\{a_1 S_1(\omega) + a_2 S_2(\omega)\} \\ &= a_1 \text{Tilt}\{S_1(\omega)\} + a_2 \text{Tilt}\{S_2(\omega)\}. \end{aligned}$$

Thus when $S(\omega) = \sum S_k(\omega)$, spectral tilt may be found as the sum of tilts from each term $S_k(\omega)$:

$$m = \sum_k \text{Tilt}\{S_k(\omega)\} = \sum_k m_k$$

To prove that the linearity property holds in this case, consider the following: when optimally fitting samples of $S(\omega)$ ($0 \leq \omega \leq \pi$) with a first-order polynomial by the method of least squares, b_{opt} and m_{opt} may be found by solving the following system of normal equations $Ax = y$:

$$\begin{bmatrix} M & \sum_{k=0}^{M-1} \omega_k \\ \sum_{k=0}^{M-1} \omega_k & \sum_{k=0}^{M-1} \omega_k^2 \end{bmatrix} \begin{bmatrix} b_{opt} \\ m_{opt} \end{bmatrix} = \begin{bmatrix} \sum_{k=0}^{M-1} S(\omega_k) \\ \sum_{k=0}^{M-1} \omega_k S(\omega_k) \end{bmatrix}$$

Here the polynomial being defined is $y(\omega) = m_{opt}\omega + b_{opt}$, and frequency values $\omega_k = k\pi/(M-1)$ ($k = 0, 1, \dots, M-1$) are M uniformly-spaced samples of ω over the interval $0 \leq \omega \leq \pi$. Vector y may be expressed as $y = V^T s$, where:

$$s = \begin{bmatrix} S(\omega_0) \\ S(\omega_1) \\ S(\omega_2) \\ \vdots \\ S(\omega_{M-1}) \end{bmatrix} \quad V = \begin{bmatrix} 1 & \omega_0 \\ 1 & \omega_1 \\ 1 & \omega_2 \\ \vdots & \vdots \\ 1 & \omega_{M-1} \end{bmatrix}$$

Vector x may be found after a single matrix multiplication: $x = A^{-1}V^T s = Ds$ (A^{-1} will always exist for unique sampled values of ω). Note that matrix D is independent of $S(\omega)$.

Since matrix multiplication is a linear operation, replacing s with a sum of terms yields:

$$\begin{aligned} x &= D \sum_{i=1}^N s_i = \sum_{i=1}^N D s_i = \sum_{i=1}^N x_i \\ &= \begin{bmatrix} b_1 + b_2 + \dots + b_N \\ m_1 + m_2 + \dots + m_N \end{bmatrix} = \begin{bmatrix} b_{opt} \\ m_{opt} \end{bmatrix} \end{aligned}$$

Thus we have proven that for polynomial fitting of sampled points by the method of least-squares, the sum of polynomial coefficients calculated to optimally fit each additive component of s equals the polynomial coefficients calculated to optimally fit s . The true spectral tilt of $S(\omega)$ is approached when the number of sample points $M \rightarrow \infty$, so this property is also valid in the continuous frequency domain.

Spectral Tilt from Cepstral Coefficients

The log power spectrum $S(\omega)$ may be expressed as a summation of cosine functions, weighted by the cepstral coefficients [4]:

$$\begin{aligned} S(\omega) &= \ln |H(e^{j\omega})|^2 = 2 \ln |H(e^{j\omega})| \\ &= 2 \sum_{k=1}^{\infty} c_k \cos(k\omega) = \sum_{k=1}^{\infty} S_k(\omega) \end{aligned}$$

Thus $S(\omega)$ is the sum of infinitely many cosine terms. Using the linearity property discussed above, we may express spectral tilt in terms of the cepstral coefficients:

$$\begin{aligned} m &= \sum_{k=1}^{\infty} m_k = \sum_{k=1}^{\infty} \text{Tilt}\{2c_k \cos(k\omega)\} \\ &= 2 \sum_{k=1}^{\infty} c_k \text{Tilt}\{\cos(k\omega)\} = \frac{-48}{\pi^3} \sum_{k=1,3,5,\dots}^{\infty} \frac{c_k}{k^2} \end{aligned}$$

Because the even-indexed cepstral coefficients are the weights for cosine waves having an integer number of periods in the range $0 \leq \omega \leq \pi$ rads/sec, there is zero contribution to spectral tilt from these terms.

Spectral Tilt from Linear Predictor Poles

The log power spectrum of an N -th order LPC filter may also be expressed in terms of its N pole values and gain constant G :

$$S(\omega) = \ln |H(e^{j\omega})|^2 = \ln \left| G \prod_{k=1}^N (1 - p_k e^{-j\omega})^{-1} \right|^2$$

$$= \ln G^2 - 2 \sum_{k=1}^N \ln |1 - p_k e^{-j\omega}|$$

In this form $S(\omega)$ is the sum of $N+1$ terms. The spectral tilt of the term $\ln G^2$ equals zero, leaving the following expression for spectral tilt of $S(\omega)$ in terms of its N pole values:

$$m = \text{Tilt}\{S(\omega)\} = -2 \sum_{k=1}^N \text{Tilt}\{\ln |1 - p_k e^{-j\omega}|\}$$

We were not able to solve the integral and express m in terms of the pole values $\{p_1, p_2, \dots, p_N\}$ directly from this equation. An alternate solution method exists, however: to first calculate cepstral coefficients from the pole values, then solve for spectral tilt by the formula derived in the previous section. The cepstral coefficients corresponding to the N -th order all-pole log power spectrum may be found as follows [5]:

$$c_k = \frac{1}{k} \sum_{n=1}^N (p_n)^k$$

Combining this result with the previous expression for spectral tilt in terms of the cepstral coefficients, we obtain the following infinite summation:

$$m = \frac{-48}{\pi^3} \sum_{k=1,3,5,\dots}^{\infty} \left\{ \frac{1}{k^3} \sum_{n=1}^N (p_n)^k \right\}$$

Fortunately, due to the p^k/k^3 terms, the solution for spectral tilt m converges rapidly with increasing k (typically, only fifteen or so terms yield a solution to full IEEE double

floating-point precision). Another LPC pole-based method is to pre-calculate spectral tilt for various combinations of pole magnitude and angle, then store the results in a look-up table. We obtained good quantization levels by uniform sampling of θ vs. $\ln(1-r)$, where $p = re^{j\theta}$.

Spectral Tilt from Linear Predictor Coefficients

The log power spectrum of an N -th order LPC filter may also be expressed in terms of its linear predictor coefficients and gain constant G :

$$S(\omega) = \ln |H(e^{j\omega})|^2 = \ln G^2 - \ln \left| 1 - \sum_{k=1}^N \alpha_k e^{-j\omega k} \right|^2$$

In this form $S(\omega)$ may not be expressed as a sum of terms, where each term depends on a coefficient α_k . The approach we take is to take advantage of a recursive solution for the cepstral coefficients from the LPC coefficients [6]:

$$c_k = \begin{cases} \alpha_k + \frac{1}{k} \sum_{n=1}^{k-1} n c_n \alpha_{k-n}, & 1 \leq k \leq N; \\ \frac{1}{k} \sum_{n=k-N}^{k-1} n c_n \alpha_{k-n}, & k > N. \end{cases}$$

The cepstral coefficients are then used to calculate spectral tilt from the formula previously derived. In most cases this method will be more computationally efficient than factoring the LPC polynomial to obtain the pole values, and solving for spectral tilt using the pole equations.

Experimental Results

We have applied the equations derived above to measuring the spectral tilt of sampled speech data: a 30 msec hanning window was stepped across the speech samples with 0.1 msec steps, the windowed data zero-padded to 1024 points prior to calculating its FFT.

The MATLAB "polyfit" routine was used to estimate the spectral tilt of 513 samples of $\ln|H(e^{j\omega})|^2$, spaced uniformly between 0 and 5 KHz. A 180 ms section of the speech waveform used for this experiment is plotted as Figure 1(a). The corresponding spectral tilt, calculated directly from $\ln|H(e^{j\omega})|^2$, is plotted as the solid line in Figure 1(b). (The slope value is expressed in dB/kHz.) This plot shows interesting spectral slope features corresponding to silence, onset and end of voiced speech, sibilant and plosive sounds.

Figure 1(a). A 180 ms section of female speech selected for analysis.

Figure 1(b). Solid line: exact spectral tilt, calculated from the log-magnitude spectrum. Dashed line: spectral tilt estimated from the poles of the corresponding LPC-14 spectral model.

Next we calculated LPC-14 coefficients corresponding to each short-time spectrum (autocorrelation method), factored the denominator polynomial to obtain pole values for each frame, and applied the formula presented above that calculated LPC spectral tilt from the pole values. The result is plotted as the dashed line in Figure 1(b). We also found that lower LPC orders provide reasonable estimates of spectral tilt, as shown in Fig. 2.

Conclusion

From the equations presented here one may calculate spectral tilt directly from various LPC model parameters, avoiding the necessity and computational expense of first calculating the log power spectrum. We rely on the linearity property of least-squares polynomial data fitting to simplify our expressions. The results may be applied to efficiently estimate the short-time spectral tilt of speech signals to help discriminate between various speech waveform components.
